ABSTRACT
We analyse the observed correlation between galaxy environment and Hα emission line strength, using volume-limited samples and group catalogues of 24968 galaxies at 0.05 < z < 0.095, drawn from the 2dF Galaxy Redshift Survey (M_r < −19.5) and the Sloan Digital Sky Survey (M_r < −20.6). We characterise the environment by 1) Σ_5, the surface number density of galaxies determined by the projected distance to the 5th nearest neighbour; and 2) ρ_1 and ρ_5, three-dimensional density estimates obtained by convolving the galaxy distribution with Gaussian kernels of dispersion 1.1 Mpc and 5.5 Mpc, respectively. We find that star-forming and quiescent galaxies form two distinct populations, as characterised by their Hα equivalent width, W_0(Hα). The relative numbers of star-forming and quiescent galaxies varies strongly and continuously with local density. However, the distribution of W_0(Hα) amongst the star-forming population is independent of environment. The fraction of star-forming galaxies shows strong sensitivity to the density on large scales, ρ_5, which is likely independent of the trend with local density, ρ_1. We use two differently-selected group catalogues to demonstrate that the correlation with galaxy density is approximately independent of group velocity dispersion, for σ = 200−1000 km s⁻¹. Even in the lowest density environments, no more than ~ 70 per cent of galaxies show significant Hα emission. Based on these results, we conclude that the present-day correlation between star formation rate and environment is a result of short-timescale mechanisms that take place preferentially at high redshift, such as starbursts induced by galaxy-galaxy interactions.

Key words: galaxies: clusters: general, galaxies: evolution, galaxies: interactions

10 February 2008
1 INTRODUCTION

The galaxy population today can be effectively described as a combination of two distinct types. The first are red, morphologically early-type galaxies with little or no current star formation; the remainder are blue, late-type galaxies with active star formation. This segregation has been known for a long time; however the superb data from the Sloan Digital Sky Survey has revealed how surprisingly distinct these two populations are, at least in terms of their colours (Strateva et al. 2001; Balogh et al. 2003). This segregation is known to be strongly mass-dependent, with the most massive galaxies being predominantly red, early-types (Knappmann et al. 2003). It is currently unclear whether galaxy evolution at the present day consists of galaxies changing from one type to another in a short time, or of evolution in properties within a given class.

Direct evidence of galaxy evolution comes from observations of galaxies at different redshifts; this shows that, in the past, the average star formation rate (SFR) was much higher (Lilly et al. 1996; Madgakly et al. 1996; Wilson et al. 2002), and the typical star-forming galaxy was more luminous (Cowie et al. 1990). Given the near-constancy of the SFR in the Milky Way (e.g. Rocha-Pinto et al. 2000), it seems likely that this downsizing effect is the main characteristic of the decline in global star formation; the most massive galaxies have recently stopped forming stars altogether, while less massive galaxies continue unhindered.

A more indirect form of evolution is observed as the change in galaxy populations as a function of their environment at a given epoch. In particular, galaxies in dense environments (i.e. clusters) tend to have early-type morphologies (e.g. Dressler 1980; Dominguez et al. 2001; Treu et al. 2003) and low SFRs (Balogh et al. 1997; Balogh et al. 1998, 1999; Gomez et al. 2003; hereafter Paper II). This segregation is known to be strongly mass-dependent, with the most massive galaxies being predominantly red, early-types (Knappmann et al. 2003). It is currently unclear whether galaxy evolution at the present day consists of galaxies changing from one type to another in a short time, or of evolution in properties within a given class.

1.1 Previous Work

Our understanding of galaxies in groups and lower density environments has been hindered by the difficulties in obtaining large, unbiased samples. Most of the work has been restricted to compact groups (e.g. Hickox 1984; Rubin et al. 1991; Iglesias-Parano & Vichiez 1994; Coziol et al. 2000; Nishiura et al. 2000; Verdes-Montenegro et al. 2001; de la Rosa et al. 2001; Kelm & Focardi 2003), which are most likely to be physically bound systems. However, these may be a special class of group, not representative of a typical stage of the hierarchy through which most galaxies evolve.

Postman & Geller (1984) analysed the morphology-density relation in groups selected from the CfA redshift survey (Geller & Huchra 1983) and demonstrated that the original relation found in clusters by Dressler (1980) extends continuously to lower densities. Below a density of ~1 Mpc$^{-3}$ ($M_{100} < -17.5$) there is no further correlation is seen. Similar trends have since been confirmed in numerous other studies (e.g. Zabludoff & Mulchaey 1998; Hashimoto & Oemler 1999; Tran et al. 2001; Treu et al. 2003). Interestingly, Postman & Geller (1984) found the trend with local density is the same in both rich clusters and poor groups; the only difference is that poor groups typically sample lower density regions and, thus, have populations more dominated by late-type galaxies. It has been argued based on this evidence that galaxy-galaxy interactions within the group environment are the mechanism responsible for the high fractions of early-type galaxies in clusters (e.g. Zabludoff & Mulchaey 1998, 2000; Hashimoto & Oemler 2000).

Less work has been done on the stellar populations of group galaxies, though there is good evidence that they are intermediate between those of the field and rich clusters (Allington-Smith et al. 1994; Girardi et al. 2004; Tran et al. 2001; Carberg et al. 2001). More recently, analysis of SFRs in galaxy groups selected from the partially-completed 2dFGRS survey has been done by Merchán & Zandivarez (2002). Based on this group catalogue, Martinez et al. (2002) found that even the lowest-mass groups, with masses ~ $10^{13}M_{\odot}$, show reduced total SFRs relative to the field. Dominguez et al. (2003) claimed that the spectral-type dependence on local density is only observed in groups more massive than $3 \times 10^{13}M_{\odot}$; however, this claim appears to arise mostly from the fact that their low-mass groups do not sample densities as high as found in the high-mass groups.

1.2 The purpose of this paper

We analyse the local correlation between star-formation activity and environment using data obtained from the...
two largest galaxy surveys ever conducted: the 2dFGRS
(Colless et al. 2001, 2003) and the SDSS (York et al. 2000).
In particular, we have selected a sample of galaxy groups
from each survey, but in significantly different ways. Since
the definition of a group is partly subjective, and a variety
of algorithms have been developed to find groups in redshift
surveys, comparing results from the two catalogues allows
us to investigate the sensitivity of our results to the way the
group catalogue is constructed.

The purpose of this paper is to establish how star forma-
tion in the galaxy population, as characterised by the dis-
tribution of Hα emission, depends on environment. Specifically,
we will investigate whether the most important variable is 1)
velocity dispersion of the embedding group or cluster; 2)
local galaxy density, on scales \( \leq 1 \) Mpc; or 3) large-scale struc-
ture, as parameterised by the density on \( \sim 5 \) Mpc scales. We
will show that the number of actively star-forming galaxies
depends on both the local and large-scale density, but that
the properties of the star-forming galaxies themselves do not.

A summary of the paper follows. In Section 2 we de-
scribe the details of the two datasets analysed herein, focus-
ing on the construction of group catalogues, measurement
of emission line strengths, and sample selection. Our results
are presented in Section 3. We discuss the physical implica-
tions of our results in Section 4, and draw some conclusions
in Section 5. Throughout the paper we use a cosmology of
\( \Omega_m = 0.3, \Omega_\Lambda = 0.7 \) and \( H_0 = 100h \) km s\(^{-1}\) Mpc\(^{-1}\), with
\( h = 0.7 \). All distances are proper lengths in units of Mpc.

2 DATA

We will use local data gleaned from the two largest redshift
surveys available: the 2dFGRS (Colless et al. 2001, 2003)
and the SDSS (York et al. 2000). Below we summarise the
data in each survey, and describe our group catalogues, emis-
sion line measurements, and sample selection criteria.

2.1 The 2dF Galaxy Redshift Survey

2.1.1 Summary of the data

The 2dFGRS has obtained over 220 000 spectra of galaxies
selected in the photographic \( b_1 \) band, from the APM galaxy
catalogue. The targeted galaxies are located in two con-
tiguous declination strips, plus 99 randomly located fields.
One strip is in the southern Galactic hemisphere and cov-
ers approximately 80° × 15° centred close to the SGP. The
other strip is in the northern Galactic hemisphere and cov-
ers 75° × 10°. The 99 random fields are located over the
entire region of the APM galaxy catalogue in the southern
Galactic hemisphere outside of the main survey strip. We
only use the contiguous fields for this work. Full details of
the survey strategy are given in (Colless et al. 2000). The
survey spectra were obtained through \( \sim 2'' \) fibres, and
cover the wavelength range 3600–8000Å at 9Å resolution.
Only the wavelength range of 3600–7700Å is used during
the line fitting procedure due to poor signal to noise and
strong sky emission in the red part of the spectrum. The
wide wavelength range is made possible by the use of an
atmospheric dispersion compensator (ADC) within the
2dF instrument (Lewis et al. 2002a). The accuracy of each
individual redshift is \( \sim 85 \) km s\(^{-1}\) (Colless et al. 2004).

2.1.2 The group catalogue

The group catalogue is based on a friends-of-friends perco-
lation algorithm, which links neighbouring galaxies together
if they lie within a specified linking-length of each other
(Eke et al. 2003). The linking-length is scaled with redshift
in order to obtain groups of a constant overdensity in the
magnitude limited survey. This is done by scaling the length
according to \( n(z)^{-1/3} \), where \( n(z) \) is the mean galaxy density
at redshift \( z \). Furthermore, the linking length along the line of
sight (\( \ell_\parallel \)) is allowed to be larger than that in the plane of
the sky (\( \ell_\perp \)), to account for the effects of peculiar velocities.
The algorithm is extensively tested on mock catalogues de-
ferred from numerical simulations with \( \sigma_8 = 0.9 \), so the com-
pleteness and contamination of the catalogue is understood.
For details we refer the reader to (Eke et al. 2003); we briefly
review the salient points here. The mock galaxy catalogues
are created using the semi-analytic models of (Cole et al.
2000), with the 2dFGRS selection function. Groups identi-
fied from this mock catalogue are then compared with the
respective “true” group, identified as galaxies populating
dark matter halos identified using a friends-of-friends
algorithm with a linking length of \( b = 0.2 \) times the mean
particle separation. The parameters of the group-finding al-
gorithm are tuned to provide the best match between the
median properties (size and mass) of the observed and true
groups. These best-fit parameters are \( b = \ell_\perp n(z)^{-1/3} = 0.13, L_{1,\text{max}} = 2 h^{-1} \) Mpc and \( R = 11 \), where \( L_{1,\text{max}} \) is the
maximum linking-length permitted across the line of sight and
\( R = \ell_\parallel/\ell_\perp \). These values are insensitive to \( \alpha \) for rea-
able values of the normalisation. Small, parameterised per-
turbations of \( b \) and \( R \) are allowed to remove small differ-
ences in the recovered properties that correlate with halo
mass. The median recovered velocity dispersions are accu-
crate to better than \( \sim 10\% \), independent of halo mass, when
compared with the velocity dispersion of the parent dark
matter halo; however, the scatter in this accuracy is large.
The catalogue is highly complete, recovering \( > 95\% \) of hal-
os with dark matter mass \( M \lesssim 4 \times 10^{14} \) M⊙; the price to be paid is some contamination from unphysical systems.
For the most massive haloes, the algorithm is susceptible
to a small amount of fragmentation; approximately \( 10\% \) of
haloes with \( M \gtrsim 10^{14} \) M⊙ are fragmented into more than
one group with mass at least 20 per cent that of the parent
dark matter halo.

For each group, we calculate the velocity dispersion us-
ing the gapper estimate of (Waller & Thissen 1979), as dis-
cussed in (Beers et al. 1990), which is insensitive to outliers.
The group centre is computed by iteratively rejecting the
most distant galaxy until only two galaxies remain; the cen-
tre of this mock catalogue are then compared with the
median properties (size and mass) of the observed and true
groups. These best-fit parameters are \( b = \ell_\perp n(z)^{-1/3} = 0.13, L_{1,\text{max}} = 2 h^{-1} \) Mpc and \( R = 11 \), where \( L_{1,\text{max}} \) is the
maximum linking-length permitted across the line of sight and
\( R = \ell_\parallel/\ell_\perp \). These values are insensitive to \( \alpha \) for rea-
able values of the normalisation. Small, parameterised per-
turbations of \( b \) and \( R \) are allowed to remove small differ-
ences in the recovered properties that correlate with halo
mass. The median recovered velocity dispersions are accu-
crate to better than \( \sim 10\% \), independent of halo mass, when
compared with the velocity dispersion of the parent dark
matter halo; however, the scatter in this accuracy is large.
The catalogue is highly complete, recovering \( > 95\% \) of hal-
os with dark matter mass \( M \lesssim 4 \times 10^{14} \) M⊙; the price to be paid is some contamination from unphysical systems.
For the most massive haloes, the algorithm is susceptible
to a small amount of fragmentation; approximately \( 10\% \) of
haloes with \( M \gtrsim 10^{14} \) M⊙ are fragmented into more than
one group with mass at least 20 per cent that of the parent
dark matter halo.

For each group, we calculate the velocity dispersion us-
ing the gapper estimate of (Waller & Thissen 1979), as dis-
cussed in (Beers et al. 1990), which is insensitive to outliers.
The group centre is computed by iteratively rejecting the
most distant galaxy until only two galaxies remain; the cen-
tre is taken to be the position of the brighter of these two
galaxies.

2.1.3 \( H\alpha \) as a star formation tracer in the 2dFGRS

The SFR is directly related to the \( H\alpha \) emission luminosity
\( (\text{e.g.} \, \text{Kennicutt} \, 1983) \), and we will use this emission line as
our tracer of star formation. To provide a reliable description
of SFR, however, Hα luminosities need to be corrected for underlying absorption, dust extinction, and aperture effects, all of which are important (e.g. Charlot & Longhetti 2001; Hopkins et al. 2001, 2003; Afonso et al. 2003). When these corrections are made, there is good agreement between Hα-derived SFRs, and those derived from the far infrared, radio or ultra–violet continuum (Hopkins et al. 2003). In this paper, however, we will focus only on the rest-frame equivalent width of the Hα line, \( W_0(\text{H} \alpha) \), corrected for underlying absorption (see below). Uniform dust extinction will not affect the \( W_0(\text{H} \alpha) \), though selective extinction around massive stars will (Charlot & Longhetti 2001). Aperture corrections to the \( W_0(\text{H} \alpha) \) depend on the spatial distribution of the Hα emission. As long as the size distribution of galaxies is independent of environment, neglecting this correction does not affect the results of this paper. We will demonstrate that this assumption is justified, in Appendix A.

As described in Paper I, all of the measurements of line equivalent widths have been performed using a completely automatic procedure. In summary, up to 20 individual absorption and emission lines are fitted simultaneously with Gaussian profiles. The Hα emission line is accurately deblended from the adjacent [Nii]\( \lambda 6548\text{A} \) and [Nii]\( \lambda 6583\text{A} \) lines; the [Nii] lines are constrained to be in emission while the Hα line may be either emission or absorption (but not both); measurements are made whether or not the line is detected in emission. We will add 1\( \AA \) to the Hα equivalent widths to approximately account for the effects of stellar absorption (Hopkins et al. 2003). This correction is not important for galaxies with significant emission, which are of interest here, but ensures that the mean \( W_0(\text{H} \alpha) \) is never much less than zero. Because of the uncertain flux calibration of the 2dFGRS spectra, we do not derive Hα luminosities, or SFRs, but restrict the analysis to the observable quantity \( W_0(\text{H} \alpha) \).

We also wish to exclude from the analysis galaxies in which most of the emission comes from an active galactic nuclei (AGN). Since the flux calibration is not reliable over long wavelengths, we just use the criterion [Nii] \( \lambda 6583/\text{H} \alpha > 0.63 \) to identify AGN-dominated spectra, when the equivalent widths of both lines are greater than 2\( \AA \) (e.g. Miller et al. 2003). Since the AGN fraction does not appear to correlate with environment, however (Miller et al. 2003), the correction does not affect any of the conclusions in this paper.

2.1.4 Sample selection

We select a volume-limited subset of the contiguous fields, where the lower redshift limit, \( z > 0.05 \), is chosen to reduce our sensitivity to aperture effects. The upper redshift limit, \( z < 0.95 \), is chosen because measurement of Hα emission becomes difficult when it is redshifted beyond \( \sim 7200 \text{A} \) and night sky emission lines are strong\(^1\). At this redshift, the magnitude limit of the survey (\( b_I = 19.45 \)) corresponds to a k-corrected luminosity of \( M_b \approx -19 \). However, for consistency with the SDSS sample (see Appendix B), we limit this sample to \( M_b = -19.5 \), using the average k-correction of Norberg et al. (2002). Finally, we exclude galaxies that are within 2 Mpc of a survey boundary; more stringent cuts are made when computing densities on various scales, as appropriate.

Our final, volume-limited sample contains 20154 galaxies. For computations of \( W_0(\text{H} \alpha) \), we exclude galaxies in which the continuum was negative, or a Gaussian was a poor fit to the line (see Paper I). Furthermore, we restrict our analysis to data taken after August 1999, since the extreme ends of spectra obtained earlier are severely affected by problems with the ADC (Lewis et al. 2002). These restrictions reduce the usable sample to 12683 galaxies. Of these, 846 (6.7\%) are identified as AGN (see Section 2.1.3 and excluded from the sample. This leaves 11837 galaxies, of which 7012 (59 per cent) are in the friends-of-groups catalogue; 1577 (13 per cent) are in groups with at least ten members above the luminosity limit, which we use for our analysis. This latter requirement is made so that meaningful estimates of local density can be made. We use the friends-of-groups linking algorithm to designate group membership, rather than selecting all galaxies within some specified radius of a chosen centre. No further selection of the clusters is made, and some of the systems are therefore dynamically unrelaxed groups, for which the velocity distribution is not a reliable indicator of dynamical mass. The velocity dispersion distribution of groups with more than ten bright members is shown in Fig. 1. As described in Section 2.1.2, this is designed to be a very highly complete catalogue that will still have some contamination from unphysical systems, though this contamination is substantially reduced by our selection of groups with at least ten members (Eke et al. 2003).

2.2 The first SDSS data release

2.2.1 Summary of the data

The SDSS (http://www.sdss.org) is a joint, 5 passband (u, g, r, i, z), imaging and medium–resolution (\( R \approx 1800 \)) spectroscopic survey of the Northern Galactic Hemisphere (see York et al. 2000, for details). In May 2003, the SDSS publicly released the first official set of data, named DR1, which comprises 186,240 spectra of galaxies, stars and QSOs over 1360 deg\(^2\) of sky. This release is fully described in Abazajian et al. (2003), and the reader is referred to Strauss et al. (2002) for a detailed description of the spectroscopic target selection for the SDSS main galaxy survey.

The spectra are obtained from 3\( \prime \) diameter fibres, larger than those of the 2dFGRS. The spectrographs produce data covering 3800-9200 \( \text{A} \), with the beam split at 6150 A by a dichroic. The spectral resolution at \( \lambda \sim 5000\text{A} \) is \( \sim 2.5\text{A} \), and redshift uncertainties are \( \sim 30\text{km s}^{-1} \).

2.2.2 The group catalogue

Groups are selected from the SDSS in a fundamentally different way from 2dFGRS groups (cf. Section 2.1.2), which allows us to test the sensitivity of our results to the group-finding algorithm. The SDSS algorithm (Nichol, Miller et al. in prep) is a semi-parametric, high dimensional technique

---

\(^1\) In Paper I we used an upper limit of \( z = 0.1 \); the small change here is made for consistency with the SDSS sample as presented in Paper II and this paper.
developed to find galaxies clustered in both position and colour. The premise is that galaxies within clusters evolve similarly, and thus galaxy clusters contain subsets of galaxies that have similar spectral energy distributions (SED). Note that this is not a red-sequence finder (e.g. Gladders & Yee 2000), and will detect groups of blue galaxies if they have similar colours. Galaxy colours are used as a proxy for the shape of the SED since they cover a larger wavelength range than the spectra and because the dimensionality of the problem is reduced to a manageable 7-d space (two spatial positions, redshift, $u-g, g-r, r-i,$ and $i-z$). In practice, we expect clustering in colour-space to be a signal from the red sequence (e.g. Gladders & Yee 2000). Galaxy overdensities in this 7-d space are found by comparing to random locations in the SDSS DR1 survey. By design, the algorithm is extremely pure (i.e. few false positives). This high purity is the result of the lack of projection in 7-d space, and the use of the False Discovery Rate statistical method in choosing a threshold above which galaxies are considered clustered (see Miller et al. 2001).

The algorithm has been tested against mock catalogues (Wechsler et al., in prep), in which galaxies are assigned $r$-band magnitudes and placed onto dark matter particles in such a way that the luminosity-dependent clustering of the SDSS seen in Blanton et al. (2003a) is matched. The remaining magnitudes are then added in so that the correlation between colour and local density, as observed in the SDSS, is also matched. The same cluster-finding algorithm used on the real data is then run on the mock catalogues. Preliminary tests show that the cluster catalogue is > 90% complete for clusters with mass $M > 2.5 \times 10^{14} M_\odot$; the completeness decreases toward lower masses. The catalogue is 100% pure for systems with $M > 5 \times 10^{14} M_\odot$ and always greater than 90% pure (Nichol, Miller et al., in prep.). We exclude groups in which the velocity distribution (measured using all galaxies, not only those identified as clustered in colour space) is significantly different from a Gaussian, so that we preferentially select dynamically isolated, relaxed systems. The final catalogue contains 104 bona-fide clusters with reliable velocity dispersions that are likely indicative of system mass. This catalogue is a good complement to the 2dFGRS catalogue, as it is a highly pure catalogue (i.e., with little contamination), at the expense of being incomplete for low-mass groups. All galaxies within $1000 \km \s^{-1}$ and twice the virial radius (defined by the galaxy number overdensity relative to the field) of the cluster are considered group members; the exact radius chosen is not important because we present our data as a function of local density, which correlates well with radius within the virialised region.

2.2.3 $H\alpha$ as a star formation tracer in the SDSS

We will again use the $H\alpha$ equivalent width as a tracer of star formation, as we have done for the 2dFGRS sample (see Section 2.1.3). Emission and absorption lines are measured automatically from the spectra by fitting multiple Gaussians where required. Again a measurement is provided for every line, whether or not it was detected in emission, and we make a 1Å correction for underlying stellar absorption [Hopkins et al. 2003]. The effect of converting $W_0(H\alpha)$ to SFR using various conversions (e.g., Kennicutt 1998 [Hopkins et al. 2001; Charlot & Longhetti 2001]), were discussed in Paper II and will not be considered here.

For the SDSS spectra we can more effectively exclude AGN (relative to the 2dFGRS), since the spectra are accurately flux calibrated. Here, we will consider the $[\text{N} \text{ii}]$/$H\alpha$ and $[\text{O} \text{iii}]$/H$\beta$ ratios, using the classification of Miller et al. (2002). Where possible, all four lines are used to identify AGN; if only one of the ratios is available, then only that one is used. Most (87%) of the AGN are identified based on the $[\text{N} \text{ii}]$/Ho ratio alone.

2.2.4 Sample selection

We will use the same volume-limited sample as in Paper II. The main criteria for selection are $0.05 < z < 0.095$ and $M_r < -20.6$ (k–corrected, for $H_0 = 70 \km \s^{-1} \Mpc^{-1}$). As for the 2dFGRS data, the lower redshift limit is imposed to minimise aperture bias due to large nearby galaxies (see Appendix A for more detail). The upper redshift limit is that where our luminosity limit equals the magnitude limit of the SDSS ($r = 17.7$; Strauss et al. 2002). From a volume–limited sample of 19287 galaxies we exclude 4237 that are within 2 Mpc of a survey boundary, and another 64 galaxies for which no reliable measurement of $H\alpha$ is available, leaving 14986 galaxies. Finally, removing a ~ 12% AGN contribution we have 13131 galaxies in the final sample. Of these, 1939 (15%) are associated with a group in the catalogue.

In Fig. 4, we show the velocity dispersion distribution for the selected subset of SDSS groups. The distribution is different from that of the 2dFGRS groups (Fig. 2), likely due to the fact that the former catalogue is incomplete at the lowest velocity dispersions, while the latter has more contamination. Furthermore, the SDSS catalogue includes a few
clusters with very high velocity dispersions, \( \sigma > 800 \text{ km s}^{-1} \), while such large systems tend to be fragmented in the 2dFGRS catalogue.

2.3 Homogeneity of the samples

In using the 2dFGRS and SDSS data together, we need to ensure that the samples are comparable in terms of selection and derived measurements. This detailed comparison is made in Appendix B. The only difference relevant to our results is that the \( b_j \)-selection of the 2dFGRS results in a sample that is more biased toward galaxies with large \( W_0(\text{H} \alpha) \) than the \( r \)-selected SDSS. Because of this difference, we will show most of our results for the two surveys separately. The final combined sample contains 24968 galaxies and 204 groups with at least ten members. Approximately 14% of all galaxies in the sample are associated with a group.

2.4 Density Estimates

The local galaxy number density around a given galaxy is not in itself a well-defined quantity. As can be anticipated from the shape of the correlation function (e.g. Baugh et al. 1996), the density of neighbouring galaxies tends to increase as you probe closer to the target galaxy (see Appendix C). We are therefore faced with two choices when characterising the density around a galaxy. One is to measure the density within a fixed distance scale. This ensures that both high- and low-density regions are measured at the same scale; however, the measurement is noisy and of limited dynamic range due to the arbitrarily small, and finite, number of galaxies within the chosen distance. On the other hand, we can use a systematically larger scale in lower density regions. This improves sensitivity and precision at low densities, but may be difficult to interpret because high- and low-density environments are measured at different physical scales. Without prior knowledge of the nature of the relevant physical effects, we cannot say which is the more meaningful estimate. For example, if we believe galaxy-galaxy interactions are important, then perhaps it is only the distance to the nearest neighbour that is relevant (Lambas et al. 2003). It is easy to imagine scenarios where either the distance to the \( N^{th} \) neighbour, or density measured on a physical scale, is likely to be more meaningful.

In this paper, we will adopt two density estimators, which are described in Appendix C. The first is a traditional projected density estimate, \( \Sigma_5 \), which is based on the projected distance to the fifth-nearest neighbour within \( \pm 1000 \text{ km s}^{-1} \). Inasmuch as we are willing to believe that galaxies can be found in discrete, relatively isolated groups, we must be cautious about interpreting our density estimate in groups where the number of members is less five. For a group with only four members, the fifth nearest neighbour will clearly not lie in the same group and, therefore, the density computed from this distance may not be what is wanted. To ensure that we maintain our intuitive idea of a local environment within groups, we only consider groups which have at least ten galaxies brighter than our luminosity limit. Furthermore, we exclude any galaxies in which the fifth-nearest neighbour is more distant than the closest survey boundary, or within \( 1000 \text{ km s}^{-1} \) of our redshift limits, to ensure accurate measurements. This may bias us against finding low-density regions, but does not affect the observed trends of galaxy property with \( \Sigma_5 \) (e.g. Miller et al. 2004).

The second estimator is a three-dimensional density \( \rho_0 \), obtained by convolving the galaxy field with a Gaussian of dispersion \( \theta \). In particular, we will consider the density measured on scales \( \theta = 1.1 \) and 5.5 Mpc (see Appendix C). These measurements underestimates the density in clusters with large velocity dispersions, but are particularly useful for probing low density regimes where peculiar velocities are small. The main disadvantage is that the signal-to-noise ratio varies with density, and is low at low densities, when there are few galaxies within the aperture. In our analysis we will therefore indicate the density at which there is less than one galaxy within the Gaussian dispersion \( \theta \), and will exclude any galaxies which are located less than 20 from a survey boundary, to avoid biasing the density estimate.

3 RESULTS

3.1 Dependence of \( W_0(\text{H} \alpha) \) on environment

In Papers I and II we showed that there is a strong correlation between \( W_0(\text{H} \alpha) \) distribution and local galaxy density. In this section we will first define precisely what property of the galaxy distribution correlates with environment; then proceed to explore how this correlation depends on the definition of local environment.

3.1.1 Bimodality in the \( W_0(\text{H} \alpha) \) distribution

In Fig. 3 we present the correlation between \( W_0(\text{H} \alpha) \) and \( \Sigma_5 \) for the 2dFGRS and SDSS samples. On the top axis we show the distance to the fifth-nearest neighbour corresponding to \( \Sigma_5 \), which shows that at the lowest densities we are measuring the galaxy distribution on \( \gtrsim 3 \text{ Mpc} \) scales, while in
the densest regions the measurement is made at $\lesssim 300$ kpc. Recall (Section 2.1) that we exclude any galaxy for which the fifth-nearest neighbour is more distant than the nearest survey boundary, or within 1000 km s$^{-1}$ of our redshift limits. The solid lines show the median and 75th percentile of the $W_0(H\alpha)$ distribution. In both cases, we reproduce the results of Paper I and Paper II; the distribution changes distinctly, at a density $\Sigma_5 \sim 2$ Mpc$^{-2}$. This is characterised by the near-total lack of galaxies with large $W_0(H\alpha)$ at densities greater than this value. At lower densities, there remains a correlation between $W_0(H\alpha)$ and $\Sigma_5$; however it is weak, with the average $W_0(H\alpha)$ increasing by only $\sim 25$ per cent over an order of magnitude in local density. The difference in normalisation between the SDSS and 2dFGRS surveys is due to the different selection criteria for the spectroscopic sample, as discussed in Appendix B.

The $W_0(H\alpha)$ distribution shown in Fig. 3 reveals the presence of two distinct galaxy populations: those with significant, ongoing star formation covering a broad range in $H\alpha$ strength (from $\sim 4\AA$ to $> 40\AA$), and those with no ongoing star formation, which form a conspicuous horizontal ridge line about $W_0(H\alpha)= 0$. This is more clearly seen in Fig. 122 where we show the $W_0(H\alpha)$ distributions as histograms. This recalls the bimodality observed in the colour distribution [Strateva et al. 2001; Blanton et al. 2003]; Baldry et al. 2003] find that the red peak distribution can be explained as the result of mergers between galaxies in the blue peak. We will therefore focus our analysis on the star-forming population, and its variation with environment.

In Fig. 4 we show the $W_0(H\alpha)$ distribution only for those galaxies with $W_0(H\alpha)> 4\AA$, in environments with the highest and lowest $\Sigma_5$ densities. The distributions are very similar; a Kolmogorov–Smirnov test cannot reject the hypothesis that the low- and high-density distributions are drawn from the same population with more than 1σ confidence. Any difference, no matter how significant, must be small: the mean $W_0(H\alpha)$ is $\sim 21.5\AA$ and $\sim 20\AA$ for the low- and high-density populations, respectively, in both the 2dFGRS and SDSS samples. Thus, the observed trend of mean $W_0(H\alpha)$ with density (Fig. 3) is due almost entirely to the relative proportion of galaxies with $W_0(H\alpha)> 4\AA$; there is at most weak sensitivity to environment within the actively star forming population alone.

3.1.2 The abundance of star-forming galaxies

Motivated by the results of the previous subsection, we show, in Fig. 5 how the fraction of galaxies with $W_0(H\alpha)> 4\AA$ depends on $\Sigma_5$. It is evident that the fraction decreases steadily with increasing density; the break at $\Sigma_5 \sim 2$ Mpc$^{-2}$ is still there, but less apparent than in Fig. 3.

Since the identification of a characteristic density can have important implications, it is useful to understand why it appears so strongly in Fig. 3 (and Papers I and II) but is much weaker in Fig. 5. Upon close examination, a change in slope is most evident in the median of the 2dFGRS, at $\Sigma_5 \sim 1$ Mpc$^{-2}$, and in the 75th percentile of the SDSS, at $\Sigma_5 \sim 3$ Mpc$^{-2}$. From Fig. 5 we see that these two densities correspond to the point at which the fraction of galaxies with $W_0(H\alpha)< 4\AA$, since this distribution is most likely dominated by measurement uncertainties, including systematic effects like stellar absorption, rather than star formation activity.

Figure 3. The dependence of $W_0(H\alpha)$ on projected, local density for the 2dFGRS (left panel) and SDSS (right panel) samples. The top axis shows the distance to the 5th nearest neighbour, from which $\Sigma_5$ is computed. The solid lines show the median and 75th percentile of $W_0(H\alpha)$, in bins of 100 galaxies. Although we only plot the data for $W_0(H\alpha)< 40\AA$, they extend to $W_0(H\alpha) \sim 100\AA$; see Fig. 124 for the full $W_0(H\alpha)$ distributions as histograms.

Figure 4. The $W_0(H\alpha)$ distribution for galaxies in the 2dFGRS (left panel) and SDSS (right panel) with $W_0(H\alpha)> 4\AA$, in low-density environments ($\Sigma_5 < 0.2$ Mpc$^{-2}$, dotted line) and high-density environments ($\Sigma_5 > 2$ Mpc$^{-2}$, solid line). We show Poisson-distributed error bars on the high-density subsample, which is the smaller of the two.
W_0(H\alpha) > 4\,\text{Å} drops below 50 (2dFGRS) or 25 (SDSS) per cent; at higher densities the median and 75th percentile, respectively, are tracing the non-star forming population with W_0(H\alpha) < 4\,\text{Å}, and the trend with \Sigma_5 largely disappears.

It is worth stressing that the trend with \Sigma_5 is fairly insensitive to projection effects, despite the fact that we are projecting over a ±14 \,\text{Mpc} cylinder, and despite the nonuniform density of the background, as we demonstrate in Appendix C1.1. To summarize the results of that Appendix, at \Sigma_5 \sim 0.1 \,\text{Mpc}^{-2}, where the projected contamination is \sim 50 per cent, we only overestimate the emission-line fraction by about 5 per cent. This is because the emission-line fraction varies weakly with \Sigma_5 at low densities, so there is little physical difference between the properties of the target galaxies and the projected galaxies. At high \Sigma_5, the projected fraction drops strongly, both because the contrast with the field is increasing, and because the radius of the projected cylinder is decreasing. Thus, the observed emission-line fraction remains within \sim 5 per cent of the true value, despite the fact that the contrast between the target and projected galaxy populations becomes large. The observed trend with \Sigma_5 is, therefore, a physical one.

Fig. 5 also shows the correlation for galaxies in groups of different velocity dispersion. We note that, although velocity dispersion gives a good indication of the group mass on average, there is a significant scatter arising because our groups are not all relaxed, spherical systems. Therefore, the velocity dispersion in some cases will be a better indicator of substructure or dynamic state than of mass. The correlation of emission-line fraction with density is present in both high- and low-velocity dispersion groups, selected from either the SDSS or 2dFGRS. There is marginal evidence (particularly in the 2dFGRS sample) that galaxies in the highest-velocity dispersion clusters have a low fraction of galaxies with W_0(H\alpha) > 4\,\text{Å} for their local density, relative to galaxies in lower-dispersion groups. Projection will have a more complex effect on this result, since the physical size of the group depends on \sigma; in particular, we expect the overestimation of both \Sigma_5 and W_0(H\alpha) to be greater in high-\sigma clusters than in low-\sigma clusters. This means the high-\sigma cluster W_0(H\alpha) distribution should exceed that of low-\sigma groups at a fixed \Sigma_5; this is opposite to what we find, and cannot therefore be the explanation for the small observed difference. Finally we note the remarkable similarity between the results for \sigma < 400 \,\text{km}\,\text{s}^{-1} groups in both samples. Since the 2dFGRS catalogue is highly complete, and the SDSS catalogue is highly pure, the persistence of a strong W_0(H\alpha)–\Sigma_5 relation in groups from both catalogues is not likely due to a selection effect.

We now consider the three dimensional Gaussian kernel density estimator with a 1.1 \,\text{Mpc} standard deviation, \rho_{1.1} (the motivation for the choice of filtering size is given in Appendix E). The \rho_{1.1} density measure allows us to find galaxies in the very lowest density environments, which are not easily measured from \Sigma_5 since that quantity projects the galaxy distribution over a 2000 \,\text{km}\,\text{s}^{-1} cylinder. In our analysis, we exclude galaxies that are within 2.2 \,\text{Mpc} of a survey boundary, for which \rho_{1.1} cannot be reliably determined; we also note that \rho_{1.1} becomes noisy when there are

\footnote{This projection corresponds to \sim 25 \,\text{Mpc}, much larger than the linear size of typical void regions.}

\(© \ 0000 \ \text{RAS, MNRAS 000, 000–000} \)
Figure 7. Galaxies in the 2dFGRS (left panel) and SDSS (right panel) are shown as a function of density computed on 1.1 Mpc and 5.5 Mpc scales, using a Gaussian filtering kernel (small dots). Galaxies in groups with $\sigma > 600\,\text{km\,s}^{-1}$ are represented as open circles, while those with $\sigma > 400\,\text{km\,s}^{-1}$ are represented as crosses. Only galaxies that are at least 11 Mpc from a survey boundary are considered. The dashed line shows the minimum reliable density; below this there are fewer than one galaxy within the filter size $\theta$ (the corresponding limit on $\rho_{2.5}$ is off the scale of the plot).

no galaxies within the filtering scale 1.1 Mpc, $\rho_{1.1} < 0.01\,\text{Mpc}^{-3}$.

Fig. 4 shows how the fraction of galaxies with $W_0(H\alpha) > 4$A depends on $\rho_{1.1}$. To approximately compare this with the corresponding $\Sigma_5$ value, we compute the projected density within a cylinder of length 2000 km s$^{-1}$ along the line of sight, to obtain an equivalent surface density, shown along the top axis. The emission-line fraction shows a strong dependence on $\rho_{1.1}$, and gets significantly steeper at $\rho_{1.1} > 0.05\,\text{Mpc}^{-3}$. However, the correlation is still present at the lowest densities observed. It is not clear whether the change in slope at $\rho_{1.1} \geq 0.05\,\text{Mpc}^{-3}$ highlights an interesting physical scale, or if $\rho_{1.1}$ simply loses sensitivity to the underlying density distribution at low densities, an effect that would be exaggerated by the logarithmic scale. Furthermore, the highest densities (which tend to correspond to clusters with high velocity dispersions) will generally be underestimated as a result of large peculiar velocities, and this may be partly responsible for the change in slope.

3.2 Local or Global Density?

We have shown that the fraction of star-forming galaxies depends strongly on the local density, measured on scales $\lesssim 1\,\text{Mpc}$, and that this correlation is approximately independent of the velocity dispersion of the embedding cluster or group. However, velocity dispersion may not be the best measurement of large-scale structure; in this subsection, we will compare densities measured on 1.1 Mpc and 5.5 Mpc scales, to determine whether $W_0(H\alpha)$ shows any independent sensitivity to structure on large-scales.

In Fig. 4 we compare the Gaussian-filtered densities $\rho_{1.1}$ and $\rho_{5.5}$ for galaxies in the SDSS and 2dFGRS samples. Galaxies are only considered if they are at least 11 Mpc from a survey boundary. In Appendix C we show that these density estimators are good tracers of intuitively dense and low-density regions, despite the complications of peculiar velocities in clusters (Fig. 4). Note that the 2dFGRS data extend to larger values of $\rho_{5.5}$ than the SDSS; these data arise from a large supercluster region at $z \sim 0.0839$ and $\alpha \sim 195.5, \delta \sim -2.9$ (J2000 degrees). Fig. 5 shows a clear separation between galaxies in groups ($200\,\text{km\,s}^{-1} < \sigma < 400\,\text{km\,s}^{-1}$) and clusters ($\sigma > 600\,\text{km\,s}^{-1}$). Galaxies in both environments span a similar range in local environment, characterised by $\rho_{1.1}$. However, galaxies in the high-velocity dispersion clusters lie at higher densities on 5.5 Mpc scales, as expected since they are physically larger systems. This is particularly true for the SDSS sample, where the groups are selected to have approximately Gaussian distributed velocities, so that there is likely to be less scatter in the relation between $\sigma$ and virial mass. Note that the higher velocity dispersions of clusters means that this pseudo-three-dimensional measurement will underestimate the density, more so than in groups. Thus the real difference between the clusters and groups is even larger than shown here.

In Fig. 5 we illustrate how the fraction of emission-line galaxies (measured from the nearest 500 galaxies in this plane) depends on these two very different density scales. Interestingly, the contours are not parallel with either axis, which indicates that the population composition shows a dependence on large ($> 5\,\text{Mpc}$) scales, in addition to the more local density measured at 1.1 Mpc. That is, the fraction of emission line galaxies is lower in regions that are overdense on 5.5 Mpc scales, even when the local (1.1 Mpc) overdensity is the same. We have checked that this is not an artifact of the smoothing or the correlation between $\rho_{1.1}$ and $\rho_{5.5}$, in the following way. For each galaxy we assign a value of $\rho_{5.5}$, chosen at random from among galaxies that have similar (within 10%) values of $\rho_{1.1}$. This preserves the correlations between $\rho_{1.1}$ and $\rho_{5.5}$, as well as between $\rho_{1.1}$ and $W_0(H\alpha)$, but removes any residual correlation between $\rho_{5.5}$ and $W_0(H\alpha)$. In this case, the contours lie nearly parallel to the $\rho_{5.5}$ axis, confirming that the correlation we see in Fig. 5 is real. There is some evidence that, at high densities, the fraction of H$\alpha$-emitting galaxies is mostly dependent on $\rho_{1.1}$, and the dependence on larger scales becomes more important at lower densities. The dependence on large-scale densities is evidently stronger than the dependence on velocity dispersion (Fig. 5), despite the correlation between them (Fig. 4).

A cautionary note needs to be added, however. Since $\rho_{1.1}$ and $\rho_{5.5}$ are intrinsically correlated, errors on these measurements can give rise to the trends shown in Fig. 5 even if the galaxy population only depends on one parameter. However, a comparison with mock catalogues strongly suggests that the observed dependence on both density scales is real (Balogh et al., in prep.).
4 DISCUSSION

4.1 Overview

Thanks to the unique size and homogeneity of the 2dFGRS and SDSS datasets, we have been able to trace the \( \lambda H\alpha \) distribution of galaxies over the full range of environments at the present day. This analysis has revealed three new, important clues about the process of galaxy formation:

1. The change in \( W_0(\lambda H\alpha) \) distribution as a function of environment is predominantly due to a change in the relative number of star-forming and non-star-forming galaxies; the \( W_0(\lambda H\alpha) \) distribution of actively star-forming galaxies themselves do not appear to depend strongly on environment. This is a surprising result which challenges theories in which the environment at the present day induces a transformation in galaxy properties, as we discuss in detail in Section 4.2.

2. The fraction of star-forming galaxies increases continuously with decreasing density. However, even at the lowest densities there is a substantial fraction of galaxies with negligible \( \lambda H\alpha \) emission; we will discuss the consequences of this in Section 4.3. There is evidence that the correlation with environment becomes steeper at \( \Sigma \gtrsim 1 \) Mpc\(^{-2} \), an effect that is also seen in the morphology-density relation (Postman & Geller 1984; Treu et al. 2003). This may represent an interesting scale at which different physics becomes important; for example, as noted by Postman & Geller (1984), at this density the typical dynamical time of the group is longer than a Hubble time, so galaxy-group interactions may start to play a role (see also Zabludoff & Mulchaey 1998, 2000).

3. The fraction of galaxies with \( \lambda H\alpha \) emission may depend not only on the local density, but also on the density on much larger scales, \( \sim 5.5 \) Mpc. If this trend is real, it means the galaxy population must be only indirectly related to its present-day environment. We discuss the implications of this in Section 4.4.

These three clues allow us to make advances in our understanding of the evolution of star formation in the Universe (Section 4.5), and of any additional physics that may take place in dense environments (Section 4.6).

4.2 Star-forming galaxies in dense environments

If galaxies at the present day are evolving as they move from low-density regions to high-density regions, we should see a signature of this transformation which depends on the relevant timescale. In particular, if all galaxies experience a gradual (\( \gtrsim 2 \) Gyr) decline in star formation when they become bound to groups or clusters (Balogh et al. 2000; Bekki et al. 2002), we expect star-forming galaxies in dense regions to show systematically lower \( W_0(\lambda H\alpha) \). Fig. 8 shows that this is not the case, implying that such a gradual decline is not a common phenomenon at the present time.

On the other hand, if the SFR declines rapidly to zero, this might not be reflected in Fig. 8 since galaxies will quickly move from the star-forming distribution to the quiescent one with \( W_0(\lambda H\alpha) < 4 \) Å. Instead, we need to look at a longer-lived tracer of star formation (i.e. one which changes slowly after star formation ceases) to observe this effect. For example, the \( \lambda H\delta \) absorption line, which remains strong for \( \sim 1 \) Gyr after star formation ceases, is a common diagnostic of recent activity. The extreme rarity (< 0.1 per cent) of bright galaxies with strong \( \lambda H\delta \) but negligible star formation at low redshift provides evidence against the possibility that SFR has recently declined on a short timescale for a signif-
icant number of galaxies [Zabludoff et al. 1996; Goto et al. 2003]; however, this depends on an accurate quantification of the duration of the enhanced Hα phase, which is systematically uncertain to within at least a factor of two. In particular, if star formation is truncated in normal spirals, without a preceding burst, the Hα line never gets very strong, and is only enhanced for a short time (e.g. Balogh et al. 1999).

In a similar way, we can use the accurate colours of the SDSS, which do not suffer from aperture bias, to trace the longer lived stellar population. In particular, we will consider the rest frame Petrosian (\(g - r\)) colour, denoted \((g - r)_0\), and use the k-corrections of Blanton et al. (2003a). To isolate the population of galaxies with recent star formation, we select blue galaxies as those with \((g - r)_0 < 0.7\), which will include any galaxy that has formed stars within the last \(\sim 300\) Myr, using the latest Bruzual & Charlot (2003) stellar population models. Fig. 2 shows the \(W_0(H\alpha)\) distribution for all such blue galaxies, compared with that of blue galaxies in groups \((\sigma = 200–400\) km s\(^{-1}\)) and clusters \((\sigma > 600\) km s\(^{-1}\)). All three distributions are consistent with being drawn from the same parent population. If cluster galaxies had slowly declining SFRs they would remain blue, but with reduced \(W_0(H\alpha)\) (e.g. Shioya et al. 2002), contrary to our observations. This reinforces our conclusions drawn from Fig. 1 that star-forming galaxies in dense environments have normal SFRs, and are not being inhibited by their environment at the present day.

However, we are still not able to rule out the possibility that the environment has caused the SFR to decline rapidly in a substantial number of cluster galaxies, as we now demonstrate. There are 617 galaxies with \(W_0(H\alpha) < 4\) A in the \(\sigma > 600\) km s\(^{-1}\) clusters. If the clusters have been constantly, and uniformly, truncating star formation in active galaxies over the last \(\sim 10\) Gyr, we would only need to find \(\sim 20\) blue galaxies with \(W_0(H\alpha) < 4\) A in clusters with \(\sigma > 600\) km s\(^{-1}\) at the present day to account for these currently inactive galaxies. This number is not inconsistent with Fig. 1 in fact there is perhaps evidence for such a population, though this may equally well be contamination from the tail of the distinct, red galaxy population at \((g - r)_0 > 0.7\). By the same argument, our results are consistent with a model in which 20 per cent of the cluster members not presently forming stars had their star formation truncated sometime within the last 2 Gyr.

Thus, the \((g - r)_0\) colour is too sensitive to recent star formation for us to put strong constraints on the number of cluster galaxies which have had their star formation truncated in the last few Gigayears. Galaxy morphology may provide a better indicator, since an observable disk structure should persist for \(> 1\) Gyr after star formation ceases (e.g. Bekki et al. 2002). Past analysis (Balogh et al. 1998; Hashimoto et al. 1998; Paper II; Paper I; Girardi et al. 2003) has indeed suggested that morphology and SFR are partly independent. Furthermore, the existence in clusters of HI-deficient spirals (e.g. Solanes et al. 2001), red, spiral galaxies with little star-formation (e.g. Poggianti et al. 1999; Balogh et al. 2002b), and spiral galaxies with unusually smooth structure (McIntosh et al. 2004) all argue for some sort of transformation of spiral galaxies to be taking place in clusters. However, many of these results are based on a fairly coarse morphological binning; therefore, we reserve drawing firm conclusions until reliable, automated morphological measurements are available for the present samples (e.g. Liske et al. 2003; Kelly & McKay 2003; Blanton et al. 2003a).

### 4.3 Isolated galaxies

Although the fraction of emission-line galaxies continually increases with decreasing density, it never gets much larger than \(\sim 70\) per cent, even in the lowest density environments studied here. In these empty regions of the Universe, environment is not likely to have played a large role in galaxy evolution; therefore many galaxies must have ceased their star-formation activity for reasons independent of their surroundings (but see below). In Fig. 10 we show the \(W_0(H\alpha)\) distribution for galaxies in the lowest-density environments, with \(r_{1.1} < 0.01\) Mpc\(^{-3}\) and \(r_{5.5} < 0.005\) Mpc\(^{-3}\), and unassociated with any catalogued group or cluster. We combine all galaxies from both the 2dFGRS and SDSS samples, and consider only those galaxies which lie at least 11 Mpc from a survey boundary. Even in these extremely sparse regions of space, only \(\sim 70\) per cent of galaxies are forming a significant number of stars, with \(W_0(H\alpha) > 4\) A, and this fraction is similar for both faint and bright galaxies\(^5\) (shown separately in Fig. 10). A possible interpretation is that the \(\sim 30\) per cent of bright, isolated galaxies with no sign of

---

\(^5\) Note that only the brightest isolated galaxies are sure to have no companions of comparable brightness, since fainter galaxies could have neighbours that are just below our luminosity limit.
star formation are fossil groups (Ponman & Bertram 1993; Mulchaey & Zabludoff 1999; Smith et al. 2003; Jones et al. 2003). Although we await morphological confirmation, we note that these galaxies do have the colours typical of elliptical galaxies, \((g-r)_0 \sim 0.75 \pm 0.05\). In this case, their isolation may be a misleading representation of environment; in fact, they may represent the most dense environments, where all bright, surrounding galaxies have merged into one.

4.4 Dependence on large-scale structure

We showed in §3.2 that, although the galaxy population depends strongly on its local environment, it may also be sensitive to the density on \(\gtrsim 5\) Mpc scales, especially at low densities. That is, fewer galaxies in supercluster-like environments have significant H\(_\alpha\) emission, relative to the density in environments with similar local densities. We currently treat this conclusion as tentative, because a similar trend could be caused by uncertainties in the correlated densities \(\rho_{1.1}\) and \(\rho_{5.5}\); however, comparison with mock catalogues strongly suggest this is not the case (Balogh et al., in prep). A similar dependence on large-scale structure has previously been observed in the morphologies of galaxies in clusters at \(z \sim 0.2\) (Balogh et al. 2002d). Using high resolution Hubble Space Telescope imaging to decompose the disk and bulge components of cluster members, Balogh et al. (2002d) found evidence that the bulges of galaxies at a fixed local density are systematically brighter in massive clusters (as traced by their X-ray emission) than in low mass clusters. On the other hand, the disk luminosity function does not show this dependence. It was suggested that bulge components grow preferentially within large-scale overdensities, perhaps due to richer merger histories, but that the disk properties are not sensitive to this structure.

However, our results show that the galaxy population depends more strongly on the large-scale density than on the mass of the embedding halo, as evidenced by the lack of correlation with cluster velocity dispersion, at a fixed \(\Sigma_v\) (Fig. 9). This, together with the results of Section 4.2 suggests that galaxy properties are only indirectly related to their environment at the present day. For example, the early-type population that dominates clusters today likely arises from the fact that galaxies in dense regions form earlier, and experience more galaxy-galaxy interactions throughout their longer lifetime, than galaxies in underdense regions (Zabludoff & Mulchaey 1998; Blanton et al. 1999; Ballard et al. 2003). Another possibility is that galaxy evolution is strongly affected by tidal forces, which arise from structure on all scales (e.g. Gnedin 2003; Moss & Whittle 2000).

4.5 Implications for the global SFR evolution

It has been proposed that changes in the typical environment, due to the hierarchical growth of structure, drive the evolution in global SFR (Balogh & Bower 2003; Bower & Balogh 2003). This hypothesis maintains that the correlation between SFR and local density remains unchanged, but galaxies at higher redshift typically lie in lower density environments. However, this interpretation is inconsistent with the present data, as we demonstrate here. The fraction of star-forming galaxies (\(W_0(H\alpha) > 4\)\(\AA\)) is \(\sim 0.4\) in the SDSS and \(\sim 0.57\) in the 2dFGRS. This is close to the maximum fraction achieved in any environment at \(z = 0\) (e.g. Figs. 5 and 6; also Section 4.3). On the other hand, the average SFR at \(z \sim 0.4\) is expected to be about 75% higher than at the present day. This can be inferred from the increase in the ultraviolet luminosity density of the Universe (e.g., Wilson et al. 2002); a similar result is obtained by comparing the average [O\textsc{iii}] equivalent width at \(z \sim 0.3\) from the CNOC surveys with that at \(z = 0\) (Paper II). To achieve such a dramatic increase in the mean SFR, either the fraction of star-forming galaxies at \(z \sim 0.4\) is much higher than anywhere at the present day, or the typical star-forming galaxy has a higher SFR. It is interesting that Treu et al. (2003) find the fraction of morphologically-classified early-type galaxies in low-density regions has not evolved substantially between \(z = 0.4\) and \(z = 0\), suggesting that evolution is of the latter type. Either way, the galaxy population at \(z = 0.4\) must be different from that in any environment at \(z = 0\).

A direct test of evolution in the SFR-density correlation is not yet possible, as intermediate- and high-redshift cluster data do not generally extend far enough from the cluster centre (Balogh et al. 1997; Couch et al. 2001; Balogh et al. 2002a,b). Kodama et al. (2001), however, have analysed multi-colour Subaru data which shows that the red sequence in the \(z \sim 0.4\) cluster Cl0024+J1347 has not evolved substantially between \(z = 0.4\) and \(z = 0\), suggesting that evolution is of the latter type. Either way, the galaxy population at \(z = 0.4\) must be different from that in any environment at \(z = 0\).
ever, any serious interpretation of this comparison should wait until comparable, spectroscopic measurements can be made of the galaxy population composition as a continuous function of density.

4.6 The physics of galaxy evolution

Based on the results presented here, it seems unlikely that a substantial fraction of the star-forming galaxy population is today undergoing a physical transformation induced by its environment. Instead, the observed trends with density at $z \sim 0$ are probably only related indirectly to their environment, and the physics which determines the final composition of galaxy groups and clusters probably took place at a much earlier time. Similar conclusions were reached by Zabludoff & Mulchaey (1998), based on the high fractions of early-type galaxies in nearby, X-ray groups. Observations of the local Universe alone can only put weak constraints on what the relevant physics might be, except to say that it is unlikely to be dominated by ram-pressure stripping (e.g. Gunn & Gott 1972; Quilis et al. 2000). This mechanism has the distinct advantage that there is good observational evidence for such activity (e.g. Veilleux et al. 1985). For reasons discussed in Section 4.2, it is unlikely that it could play any role in the closest-density environments.

Similarly, it may be difficult to interpret our results in the context of models in which SFR declines slowly in galaxy environments, and the physics which determines the final composition of star-forming galaxies has the distinct advantage that there is good observational evidence for such activity (e.g. Veilleux et al. 1985; Veilleux et al. 1990). For reasons discussed in Section 4.2, it is unlikely that it could play any role in the closest-density environments.

5 CONCLUSIONS

We have made a joint analysis of 24968 galaxies selected from the SDSS and 2dFGRS. The distribution of $W_0(\text{H}\alpha)$ among these galaxies is bimodal, consisting of an active population of galaxies with $W_0(\text{H}\alpha) > 4$ Å, and a quiescent population with no significant star formation at the present day. We have investigated how this distribution depends on environment, as characterised by:

- The projected surface number density of galaxies $\Sigma$, determined from the distance to the fifth-nearest neighbour.
- The three-dimensional number density of galaxies measured on 1.1 Mpc and 5.5 Mpc scales, $\rho_{1.1}$ and $\rho_{5.5}$.
- The velocity dispersion of the embedding structure, as determined from the group catalogues of Eke et al. (2003) and Nichol, Miller et al. (in preparation).

We use these different measurements of environment to establish the scales and structures on which the present-day galaxy population depends. Our findings are summarised as follows:

1. The distribution of Hα line strength for the star-forming population, selected on $W_0(\text{H}\alpha)$ or $(g - r)$ colour, does not itself depend strongly on environment. Thus, it is unlikely that SFRs are gradually decreasing in a substantial number of star-forming galaxies in or near dense environments today.

2. We note that there is no observed correlation between the fraction of AGN and environment at the present day (Miller et al. 2003). This is puzzling, especially in the context of models where star formation and AGN activity are both linked to the availability of cold gas (Kauffmann & Haehnelt 2000). It appears that star formation activity must stop (or become undetectable) when there is still some cold gas left. One possibility is that the gas density drops below a certain threshold necessary for star formation (e.g. Kennicutt 1989). For a more complete picture, we refer the reader to the subsequent paper (Balogh et al., in prep.).
2. The fraction of galaxies with $W_0(H\alpha) > 4\AA$ decreases steadily with increasing local density. There is evidence that it decreases more strongly at densities exceeding $\Sigma_5 \sim 1$ Mpc$^{-2}$, or $\rho_{1} \simeq 0.05$ Mpc$^{-3}$. The persistence of this correlation at low densities means that ram-pressure stripping, at any redshift, cannot be the only physical mechanism at work.

3. The fraction of galaxies brighter than $M^* + 1$ with $W_0(H\alpha) > 4\AA$ is never more than $\sim 70$ per cent, even in the least dense environments explored here. We have shown that this means the recent decline in globally-averaged star formation rate cannot be wholly due to the growth of large scale structure.

4. The emission-line fraction of a galaxy population appears to depend both on the local environment (on $\sim 1$ Mpc scales) and on the large-scale structure as parameterised by the density $\sim 5.5$ Mpc scales. There is little further dependence on the velocity dispersion of the group or cluster in which the galaxy is embedded. This result suggests that the composition of the galaxy population today is likely related indirectly to its present environment (see also Zabludoff & Mulchaey 1998, 2000).

The most likely physical explanations for the correlation between $W_0(H\alpha)$ distribution and environment at $z = 0$ are those which are effective over a large range of environment, affect the SFR on short ($< 1$ Gyr) timescales, and were much more effective in the past. As suggested by the previous authors (e.g. Zabludoff et al. 1996, Mulchaey & Zabludoff 1997, Hashimoto et al. 1999, Hashimoto & Oemler 2000), one good candidate is starbursts induced by galaxy interactions, since close pairs of galaxies are the only environment known to directly provoke a physical transformation. Such interactions will likely be more common at high redshift, and will have had more time to influence galaxies that end up in high density environments.

ACKNOWLEDGEMENTS

We gratefully acknowledge the efforts of all persons whose contributions led to the success of the 2dFGRS and SDSS, which in turn have made this work possible. In addition, MLB acknowledges helpful discussions with Ann Zabludoff, Tadayuki Kodama, Masayuki Tanaka and Diego Lambas; also, he thanks Carolyn M’Coey for a careful reading of the manuscript which substantially improved its clarity. MLB and RGB acknowledge financial support from PPARC fellowships, numbered PPA/P/S/2001/00298 and PPA/Y/S/2001/00407, respectively. WJC acknowledges the financial support of the Australian Research Council throughout the course of this work.

APPENDIX A: APERTURE EFFECTS

Since the spectra are obtained from 2′ (2dFGRS) or 3′ (SDSS) fibres, they do not represent the light from the whole galaxy. In particular, our measurements of Hα flux will underestimate the flux from the galaxy as a whole; we refer to this as the aperture bias. Aperture bias will not impact on our results if the average galaxy size does not correlate strongly with environment. We test this in Fig. A1 where we plot the SDSS galaxy Petrosian radius as a function of Σ and of group velocity dispersion. Note that Hopkins et al. (2003) find the amount of emission line flux lost due to aperture bias in the SDSS is a factor ~ 2 for galaxies with radius ~ 3′, increasing to a factor ~ 10 for galaxies with radius > 12′. However, there is no significant trend of galaxy size with environment. Therefore, although the absolute values of the W0(Hα) may be affected6 by aperture bias, the relative trends as a function of environment are secure. This conclusion requires the further assumption that the spatial distribution of star formation in a galaxy depends only on its SFR, and not its environment. For example, if star formation in cluster galaxies is more concentrated than for galaxies in the field with similar SFRs (e.g. Moss & Whittle 1993, 2000), the aperture corrections for cluster galaxies should be smaller.

APPENDIX B: DETAILED COMPARISON OF THE CATALOGUES

Here we compare the 2dFGRS and SDSS samples in detail. The most important difference between them for our purposes is that the 2dFGRS is selected from by photometric magnitudes, while the SDSS is selected from digital photometry. The SDSS survey is somewhat shallower, and our volume-limited sample is complete to M = −20.6. From the tables of Fukugita et al. (1995), an Sab galaxy at z = 0.06 has a colour (b − r) = 1.13, so we adopt a magnitude limit of Mb = −19.5 for the 2dFGRS sample; the survey is actually complete to 0.5 magnitudes fainter than this.

In the area of sky covering approximately 155 < α < 220 and −3 < δ < 1.5 degrees, the 2dFGRS and SDSS surveys overlap. We can use this overlap region to directly compare the galaxy and group catalogues. In our volume-limited subsample, we find 1029 galaxies in common between the two surveys (within 2′ and 100 km s$^{-1}$ of one another). The distribution of the difference between the absolute 2dFGRS b and the absolute SDSS r magnitude are shown in Fig. B1. The average colour is M(r − σ) = 0.95, similar to the colour we expected (see above). Thus we can be confident that our magnitude limits are matched as closely as possible. However, the 1σ standard deviation in colour is ~0.35; thus there will be large numbers of galaxies at the

---

6 Note that W0(Hα) is not necessarily underestimated, as it is a relative quantity. The effect of aperture bias depends on the spatial distribution of star formation; if it is uniform, W0(Hα) is not affected by this bias.
faint limit of one catalogue that will not be included in the other.

The consequences of this are shown in Fig. B2, where we compare the distributions of $W_0(\text{H} \alpha)$ in the two samples. Recall that an absorption correction of 1 Å has been applied to all measurements (see Section 2). The two distributions are very similar; however, there are relatively more galaxies with substantial Hα emission in the 2dFGRS sample. The mean equivalent width is 8.1 Å in the SDSS, and 11.9 Å in the 2dFGRS; a similar difference is seen in the 75th percentiles, which are also $\sim$ 30% larger in the 2dFGRS sample. The larger errors on the 2dFGRS spectra also result in a larger population of galaxies with $W_0(\text{H} \alpha) < 0$ Å, at the expense of galaxies in the peak (with $W_0(\text{H} \alpha) = 0$ Å).

The difference in Fig. B2 is due entirely to the blue selection of the 2dFGRS. In Fig. B3 we directly compare the $W_0(\text{H} \alpha)$ for galaxies in common between the two surveys. Most (67%) of the measurements are within 2 Å of one another. In the mean, the SDSS measurement of $W_0(\text{H} \alpha)$ is 0.6 Å larger than that of the 2dFGRS. This difference is too small (and in the wrong sense) to account for the difference in Fig. B2. We also show the comparison for galaxies at $z < 0.075$ and $z > 0.085$; there is no discernible difference between them. Since the 2dFGRS and SDSS use different size fibres, this gives added confidence that aperture effects do not have a large influence on our results.

We can also make a direct comparison between the group catalogues. In Fig. B4 we show the positions of groups in both surveys, within a $10^\circ \times 7^\circ$ region. In both cases we show all groups within $0.05 < z < 0.095$ and with $\sigma > 200$ km s$^{-1}$ and at least ten members above our luminosity limit. For the SDSS we show all the groups satisfying these criteria; however, in this paper we have only used those with well-determined velocity dispersions, shown as the solid circles. Within the full overlap region there are 29 such 2dFGRS groups, compared with 24 SDSS groups; 16 of the latter have well-determined velocity dispersions. The radii of the circles represents the cluster virial radius, estimated from the velocity dispersion as $R_{\text{vir}} = 3.5\sigma(1+z)^{-1.5}$ (Girardi et al. 1998). The correspondence between the two group catalogues is remarkably good.
keeping contamination low. We choose \( N = 5 \) to be similar to that defined by Dressler (1980), who used \( N = 10 \) before background subtraction.

\subsection{C1.1 Projection effects}

Our density estimator \( \Sigma_5 \) is a projected quantity, including all galaxies within \( \pm 1000 \) km s\(^{-1}\) of the target galaxy, or \( \pm 14 \) Mpc for \( H_0 = 70 \) km s\(^{-1}\) Mpc\(^{-1}\). We will use the 2dFGRS as an example (an analogous calculation can be done for the SDSS) and estimate the contamination at a given measured density \( \Sigma_5 \) by assuming background galaxies are distributed at the mean galaxy density. From the galaxy luminosity function of Norberg et al. (2002), we calculate that the number of galaxies within a projected cylinder of radius \( d \) is \( \sim 0.17d^2 \). If we take \( d_5 \) to be the distance to the fifth-nearest neighbour, then the fraction of projected galaxies within \( d_5 \) is given by \( f_{\text{proj}} = 0.17/(\pi \Sigma_5) \). This varies from 100 per cent at \( \Sigma_5 = 0.054 \) Mpc\(^{-2}\) (which therefore represents the field density) to 5 percent by \( \Sigma_5 = 1 \) Mpc\(^{-2}\). In environments typical of the field, the fraction of emission-line galaxies is \( \sim 70 \) per cent (Fig. 5). Therefore, the true, unprojected emission-line fraction, \( f_{\text{em}} \), is related to the observed fraction \( f_{\text{obs}} \), by \( f_{\text{em}} = (f_{\text{obs}} - 0.7f_{\text{proj}})/(1 - f_{\text{proj}}) \). In Figure C1 we show how the ratio \( f_{\text{em}}/f_{\text{obs}} \) depends on \( \Sigma_5 \). The correction is small, \( \lesssim 5 \) per cent at all values of \( \Sigma_5 \). We also show how this ratio changes if we assume the background is ten times more dense than the average, which might be the case in the vicinity of clusters and groups. However, in this case we should adopt a smaller intrinsic emission-line fraction, because the projected galaxies are themselves in a more dense environment; based on Figure 5 we take this to be 60 per cent. Even in this case, the correction required to account for projection is \( \lesssim 25 \) per cent for \( \Sigma_5 > 1 \) Mpc\(^{-2}\). In reality, such a dense field projection is probably only reasonable at the highest \( \Sigma_5 \), where the correction is \( \lesssim 5 \) per cent. We conclude that projection will only have a small effect on the trends observed in Fig. 5 and similar figures.

\subsection{C2 Fixed scale estimates: kernel density estimation}

In this section, we will consider density estimates within a fixed distance of a galaxy. We will use a Gaussian filtering kernel which has some weight in the wings, so that more weight is given to galaxies which are closer, while there is still sensitivity to more distant structures. A rigorous statistical analysis shows that the density estimate, for any data distribution, is sensitive mostly to the bandwidth \( \theta \) of the smoothing kernel, and much less sensitive to the shape of the kernel Silverman (1986). The strong bandwidth dependence is shown explicitly in Fig. C2 where we plot the average density as a function of \( \theta \). Four curves are shown, corresponding to the four quartiles of the density distribution evaluated at \( \theta = 2 \) Mpc. In general, smaller bandwidths result in greater densities. Thus, what do we choose for the optimal bandwidth? In abstract terms, the problem is to find an estimate \( f \) of the underlying density distribution function \( f \) which minimises the average value of the mean squared error:

\[ MSE(f, \hat{f}) = \left\langle \int [f(x) - \hat{f}(x)]^2 \, dx \right\rangle. \]  

\[ \text{(C1)} \]
Figure C1. The ratio between the true fraction of emission line galaxies ($W_0(H\alpha) > 4$ Å) and the observed fraction, which is contaminated by projection along the line of sight, for the 2dFGRS. The solid line represents the case where the projected galaxies are at the average density of the Universe, while the dotted line is calculated assuming this density is ten times larger.

Figure C2. The dependence of three-dimensional density estimate on bandwidth, for the combined sample. Here, the bandwidth is the standard deviation of the kernel. The sample is divided into four based on the quartiles of the density at $\theta = 2$ Mpc. Thus, the top curve shows the average density of the 25% of galaxies which have the greatest density at $\theta = 2$ Mpc, while the bottom curve corresponds to the 25% with the lowest density at that point.

Figure C3. The least-squares cross validation score (arbitrarily scaled), as a function of bandwidth, for the SDSS and 2dFGRS samples (solid and dotted lines, respectively). Both curves show a clear minimum near $\sim 1.1$ Mpc.

We want to use the data itself to find the optimal bandwidth, $\theta$, which minimises this error. Since $\int f^2(x)dx$ does not depend on $\theta$, this corresponds to minimising the function:

$$J(\theta) = \int \hat{f}^2(x)dz - 2 \int \hat{f}(x)f(x)dx. \quad (C2)$$

The method of least-squares cross-validation uses the data $X_i$ to obtain an unbiased estimate of this function:

$$\hat{J}(\theta) \approx \frac{1}{\theta n^2} \sum_i \sum_j K^* \left( \frac{X_i - X_j}{\theta} \right) + \frac{2}{n\theta} K(0), \quad (C3)$$

where $K(x)$ is the kernel function, and $K^* = K(x) * K(x) - 2K(x)$ (Wasserman et al. 2001). This function can be computed using the fast Fourier transform (Silverman 1986), but this method is relatively slow, and can be inaccurate due to a number of necessary approximations. We have implemented a new, substantially improved algorithm based on adaptive computational geometry and a hierarchical finite-difference approximation (Gray & Moore 2003a,b).

We performed a cross-validation analysis of our volume-limited, combined sample. We use a Gaussian kernel for the cross-validation, but recall that the optimal value of $\theta$ is insensitive to the exact kernel choice. Here, we are computing three-dimensional densities $\rho_\theta$, assuming the redshifts indicate line-of-sight position in a $\Lambda$ CDM model, and ignoring the effects of redshift distortions. Fig. C3 shows the least-squares value as a function of bandwidth. We see that the optimal bandwidth is $\sim 1.1$ Mpc, which we will therefore use as our best estimate of the three-dimensional local density. To measure the sensitivity of galaxy properties to larger scales, though, we will also consider densities measured on 5.5 Mpc scales, $\rho_{5.5}$.

Note that the density estimate at a given galaxy may be arbitrarily low, since the density at that point is mea-
sured from the surrounding data, not including the point itself. Densities become significantly underestimated if the width of the Gaussian, $\theta$, is comparable to the distance to the nearest boundary. We therefore only consider galaxies farther than $2\theta$ from a survey boundary when using these estimators.

To see more directly what the density estimates on different scales are measuring, we show, in Fig. C4, pie-diagrams for a section of the 2dFGRS. In each diagram, we show all galaxies that lie at least 11 Mpc from the survey boundary\(^7\). Marked as thick, black circles are galaxies in different density environments, as labelled. For each of the three density estimators, we show galaxies in the highest and lowest $\sim 6$ per cent density environments. High values of both $\Sigma_5$ and $\rho_{1.1}$ are good at finding relatively small, but dense clumps. At low densities, both estimators are good at finding isolated galaxies; however, $\Sigma_5$ is unable to distinguish truly isolated galaxies from those in low-density filaments in the plane of the sky, while $\rho_{1.1}$ measures as low-density some cluster galaxies that are elongated along the line of sight. In contrast with these, $\rho_{5.5}$ is sensitive to much larger scales. The densest galaxies, as measured on this scale, are only those in the massive supercluster, while the lowest-density environments are true voids, far from filaments or clusters.

\(^7\) This motivates our choice to show the 2dFGRS data rather than the SDSS data. The SDSS DR1 catalogue is much more patchy, and there are few large, contiguous regions where all galaxies are at least 11 Mpc from a boundary.
